Bayesian Learning Using Automatic Relevance Determination Prior with an Application to Earthquake Early Warning

Chang Kook Oh¹; James L. Beck²; and Masumi Yamada³

Abstract: A novel method of Bayesian learning with automatic relevance determination prior is presented that provides a powerful approach to problems of classification based on data features, for example, classifying soil liquefaction potential based on soil and seismic shaking parameters, automatically classifying the damage states of a structure after severe loading based on features of its dynamic response, and real-time classification of earthquakes based on seismic signals. After introduction of the theory, the method is illustrated by applying it to an earthquake record dataset from nine earthquakes to build an efficient real-time algorithm for near-source versus far-source classification of incoming seismic ground motion signals. This classification is needed in the development of early warning systems for large earthquakes. It is shown that the proposed methodology is promising since it provides a classifier with higher correct classification rates and better generalization performance than a previous Bayesian learning method with a fixed prior distribution that was applied to the same classification problem.

Introduction

Classification is a subtopic of machine learning which can be defined as “the act of taking in raw data and taking an action based on the category of the data” (Duda et al. 2000). By using a given training dataset, a separating boundary is identified that separates different-class data in the feature space, then the category to which new data belong is decided by using that separating boundary.

This classification is performed in the following three phases:

1. Phase I (feature extraction phase): this phase distills a small number of features from a large set of data that are thought to characterize each class of interest in the data;
2. Phase II (training phase): this phase identifies a separating boundary based on extracted features that are most relevant to the data classification, usually using some form of regularization; and
3. Phase III (prediction phase): in this phase, a prediction is made using the separating boundary from the previous phase to decide to which class new data belong.

Bayesian methods for classification problems have the advantage that they make probabilistic predictions (rather than giving only a possibly misleading yes/no answer) for the class that corresponds to a given feature vector (Bishop 2006). These predictions are based on a rigorous Bayesian learning procedure that rests on the axioms of probability. The essential ingredients are a set of predictive probability models involving a parameterized separating boundary function and a probability model (the prior distribution) over this set. The prior can be pragmatically chosen by the user to regularize the ill-conditioned problem of identifying a boundary that separates the classes in the feature vector space. In the absence of such regularization, the training phase will be usually lead to “over-fitting” of the data, so that generalizations beyond the training data in the prediction phase will perform poorly.

In this paper, the novel method of “Bayesian learning with automatic relevance determination (ARD) prior” is presented and illustrated for an interesting classification problem in earthquake early warning systems (Yamada et al. 2007) because of its exceptional regularization ability (Mackay 1994; Oh and Beck 2006; Tipping 2004). The Bayesian approach presented is useful for other problems of data-based classification in earthquake engineering and structural health monitoring, such as liquefaction for sandy soil sites based on soil properties and ground shaking intensity, classifying damage states based on sensor data (Oh and Beck 2006), etc. In the application presented here, the Bayesian learning method with ARD prior provides an algorithm for probabilistic predictions of whether the seismic ground motion signal that is transmitted from a seismic sensor network corresponds to near-source or far-source ground motion with respect to the causative fault. This information is important for an early warning system when it is automatically estimating the location and magnitude of the earthquake in real time (Yamada et al. 2007). Since an earthquake is a sudden event that comes without much warning, there is increasing research interest in automated seismic early warning systems that can take rapid actions to mitigate dam-

age and loss before the onset of the damaging ground shaking at a facility (Allen and Kanamori 2003; Cua 2005; Grasso et al. 2007). Seismic early warning is based on the principle that an automated and reliable system may allow time for taking mitigation measures because the speed of the most damaging S-waves (about 3.5 km/s) is slower than that of electrically transmitted signals from the seismic network sensors (about 300,000 km/s) that detect the onset of the event.

A recently developed method for an early warning system, called the virtual seismologist (VS) method (Cua 2005), can estimate the location of the epicenter and the magnitude within a few seconds after the detection of the P-waves near the causative fault. This VS method, however, currently works for moderate earthquakes of magnitude less than about 6.5 because it assumes a point-source model for the rupture (Cua 2005). To construct a seismic early warning system dealing with larger earthquakes, knowledge of the fault geometry is essential and an important ingredient in establishing the extent of the rupturing fault is to be able to estimate whether the station is close to the fault (near-source) or at some distance (far-source) based on the waveform data available at the given station (Yamada et al. 2007).

The earthquake dataset and the extracted features are described in the next section and then the training and predicting phase with the Bayesian learning procedure is described. The results obtained by the proposed method for near-source (NS) versus far-source (FS) classification are presented and compared with those from a recent related study (Yamada et al. 2007) with the conclusions following at the end.

Feature Extraction for Training Data

We chose the dataset used previously by Yamada et al. (2007). It consists of 695 strong-motion records from nine earthquakes of magnitude greater than 6.0: Imperial Valley (1979), Loma Prieta (1989), Landers (1992), Northridge (1994), Hyogoken-Nanbu (1995), Izmit (1999), Chi-Chi (1999), Denali (2002) and Niigataken-Chuetsu (2004). Records are categorized as NS if the corresponding station is less than 10 km from the fault rupture and FS otherwise. Only stations with fault distances less than 200 km are included since otherwise the ground motion amplitudes are small, resulting in a low signal-to-noise ratio. The precise number of NS and FS records for each earthquake is listed in Table 1. For each baseline-corrected time history in the dataset, the values of peak jerk, acceleration, velocity, and displacement in the horizontal and vertical directions were extracted by taking numerical derivatives or integrals when necessary (Yamada et al. 2007). We note that jerk is defined as the rate of acceleration change and so it is computed as the derivative of acceleration with respect to time. Motions with higher-frequency content such as acceleration and jerk are more informative about the fault distance, since the amplitudes of these motions decay more rapidly than those of lower-frequency motions such as displacements and velocities (Hanks and McGuire 1981). For the two horizontal components of each record, the square root of the sum of squares of the peak quantities were used. Since the peak amplitudes are utilized for classification, the peak of the S-wave needs to have arrived at a given station before predictions with the Bayesian classifier can be made.

This data processing leads to the eight extracted features listed in Table 2 for each of the 695 records. These features are combined into a vector $\mathbf{z} \in \mathbb{R}^8$:

$$
\mathbf{z} = [\log_{10} H_r, \log_{10} Z_r, \log_{10} H_a, \log_{10} Z_a, \log_{10} H_v, \log_{10} Z_v, \\
\log_{10} H_d, \log_{10} Z_d]^T
$$

where $H$ and $Z =$ peak horizontal and vertical components and $r$, $a$, $v$, and $d =$ jerk, acceleration, velocity, and displacement, respectively. The dataset of feature vectors is the same as that used in Yamada et al. (2007) where a Bayesian classification scheme was applied that used a fixed prior.

### Bayesian Learning and Prediction

Let $\mathcal{D}_N = \{(\mathbf{x}_n, y_n) : n = 1, \ldots, N\} = (\mathbf{X}, \mathbf{y})$ denote the data with features (predictor variables) $\mathbf{x}_n \in \mathbb{R}^m$ and labels $y_n \in \{0, 1\}$ (for NS-data, $y_n = 0$ and $y_n = 1$ for near-source data, $N = 695$, and $m = 8$ in our application).

Suppose that the function characterizing the separating boundary between the two classes is taken as a linear combination of features $\chi = [x_1, \ldots, x_m]^T$ with unknown coefficients $\theta = [\theta_0, \theta_1, \ldots, \theta_m]^T \in \mathbb{R}^{m+1}$:

$$f(\chi | \theta) = \sum_{j=1}^m \theta_j x_j + \theta_0$$  \hspace{1cm} (1)

The separating boundary function $f(\chi | \theta)$ is also called the (linear) discriminant function. We note in passing that the method presented here also works if the $x_j$ in Eq. (1) are replaced by nonlinear functions $g_j(\chi)$. For a known parameter vector $\theta$, the separating boundary between the different classes (NS and FS in our application) is defined as $f(\chi | \theta) = 0$ and probabilistic predictions of the class label $y \in \{0, 1\}$ corresponding to extracted features $\chi$ will be based on the probability model

$$P(y | \chi, \theta) = \begin{cases} \phi(f(\chi | \theta)), & \text{if } y = 1 \\ 1 - \phi(f(\chi | \theta)), & \text{if } y = 0 \end{cases}$$  \hspace{1cm} (2)

where $\phi(\cdot) = [0, 1]$-monotonically increasing sigmoid function on $\mathbb{R}$ defined by $\phi(x) = 1/(1 + e^{-x})$ so $\lim_{x \to -\infty} \phi(x) = 1$, $\lim_{x \to \infty} \phi(x) = 0$, and $\phi(x) + \phi(-x) = 1$ (see Fig. 1). Thus, when $f(\chi | \theta)$ is large and positive, the probability is near 1 that $\chi$ corresponds to an instance of the $y = 1$ class, while when $f(\chi | \theta)$ is negative with large magnitude, $\chi$ corresponds to an instance of the $y = 0$ class with probability near 1. Note that the boundary $f(\chi | \theta) = 0$ corresponds to a probability of 0.5 for both classes and it is invariant to a scaling of $f$; however, this scaling is important because it controls how rapidly the probability of a class approaches its asymptotic values of 0 and 1 as the feature vector $\chi$ is moved away from the boundary.

**Bayesian Learning**

Since Eq. (1) is just a model for the separating boundary, there are no true values of $\theta$ to be “estimated” but we can learn about how plausible its various values are by Bayesian updating using the data $D_N$.

From Bayes’ theorem

$$p(\theta | D_N, g) = \frac{p(D_N | \theta) p(\theta | q)}{p(D_N | g)}$$  \hspace{1cm} (3)

where $p(\theta | D_N, g)$, $p(D_N | \theta)$, $p(\theta | q)$ and $p(D_N | g)$ = posterior, likelihood, prior, and evidence, respectively. The hyperparameters $\alpha$ define the ARD prior as explained shortly.

The likelihood $P(D_N | \theta)$ measures how well the predictive probability model defined by $\theta$ predicts the actual data

$$P(D_N | \theta) = \prod_{n=1}^N p(y_n | g, \theta) = \prod_{n=1}^N \phi(f(\chi_n | \theta))^{y_n} (1 - \phi(f(\chi_n | \theta)))^{1-y_n}$$  \hspace{1cm} (4)

The prior $p(\theta | q)$ provides a means of regularizing the learning process. A novel feature of this work is the introduction of the ARD prior (Mackay 1994; Tipping 2004), which is simply a Gaussian probability density function (PDF) with mean $\hat{q}$ and covariance matrix $A(q)^{-1} = \text{diag}(\alpha_1, \ldots, \alpha_m)$

$$p(\theta | g) = (2\pi)^{-(m+1)/2} |A(q)|^{1/2} \exp\left\{-\frac{1}{2} \theta^T A(q) \theta\right\}$$  \hspace{1cm} (5)

The previous study by Yamada et al. (2007) adopted a fixed and noninformative prior that assigned the same value for all $\alpha_i$, i.e., $\alpha_i = 100^{-2}$, $i = 0, \ldots, m$, while the ARD prior uses an independent $\alpha_i$ for each parameter $\theta_i$ and these independent $\alpha_i$ are estimated during the learning process. The ARD prior combined with Bayesian model class selection plays an important role in selecting the significant features by utilizing only a small number of relevant features and automatically pruning the remaining features, instead of considering all possible model classes, one after another, as in Yamada et al. (2007).

The hyperparameter $\alpha \in \mathbb{R}^{m+1}$ can be viewed as defining a model class $M(q)$ consisting of the set of predictive probability models $\{P(y | \chi, \theta) : \theta \in \mathbb{R}^{m+1}\}$ along with the above prior PDF $p(\theta | q)$ over this set. We will then use model class selection based on the evidence $P(D_N | g)$ for $M(q)$ to select the most probable model class $M(\hat{q})$ based on data $D_N$ (Beck and Yuen 2004; Mackay 1992). It was shown by Tipping (2004) that the ARD prior suppresses ill-conditioning by discouraging strong correlations between terms in Eq. (1) that are not supported by the data; in fact, it may happen that some $\alpha_j \to \infty$ during the optimization to find $M(\hat{q})$ which completely suppresses the corresponding terms in Eq. (1) [i.e., $\theta_j = 0$ since for $M(\hat{q})$, $\theta_j$ has a Gaussian prior with zero mean and vanishing variance].

The next step is to construct a Gaussian approximation of the posterior $p(\theta | D_N, g)$ using Laplace’s asymptotic approximation (Beck and Katafygiotis 1998; Mackay 1992). This is achieved by making a quadratic approximation of the log-posterior around the most probable value, $\hat{\theta}$, given by maximization of the posterior PDF. This produces a Gaussian distribution with mean $\hat{\theta}$ and covariance matrix $\hat{\Sigma}$ which is the inverse of the negative of the Hessian matrix of the log-posterior.

The detailed procedure for the Laplace approximation is as follows (Oh 2007):

1. For a given value of $\alpha_i$, the log-posterior from Eqs. (3)–(5) is (ignoring irrelevant additive terms that depend only on $\alpha_i$):

Fig. 1. Shape of sigmoid function
\[ \ln[p(\theta|D_N, g)] = \sum_{n=1}^{N} \ln[P(y_n|\theta, x_n)] + \ln[p(\theta|g)] \]
\[ = \sum_{n=1}^{N} \left[ y_n \cdot \ln \phi_n(\theta) + (1 - y_n) \cdot \ln(1 - \phi_n(\theta)) \right] \]
\[ - \frac{1}{2} \theta^T A(\theta) \theta \tag{6} \]

where \( A(\theta) = \text{diag}(\alpha_0, \alpha_1, \ldots, \alpha_N) \) and \( \phi_n(\theta) = f_\theta(x_n) \). By using an iterative procedure based on a second-order Newton method (or any other optimization method), the most probable values \( \hat{\theta}(g) \) are estimated by maximizing \( \ln[p(\theta|D_N, g)] \).

2. The inverse covariance matrix is \( \Sigma^{-1}(g) = -\nabla_\theta \nabla_g \ln p(\theta|D_N, g) \) evaluated at \( \hat{\theta}(g) \) and the resulting Gaussian approximation of the posterior distribution is
\[ p(\theta|D_N, g) \approx (2\pi)^{-\left(m+\frac{1}{2}\right)} |\Sigma|^{-1/2} \exp\left\{ -\frac{1}{2} (\theta - \hat{\theta})^T \Sigma^{-1}(\theta - \hat{\theta}) \right\} \tag{7} \]

where \( \hat{\Sigma}(g) = (\Phi' B \Phi + A)^{-1} \) is the inverse covariance matrix for \( g \), given \( g \); \( \hat{\theta}(g) = \hat{\Sigma} \Phi' B \Phi (\Phi' B \Phi + A)^{-1} \) is the most probable value of parameter \( g \), given \( g \); \( \Phi = \begin{bmatrix} \Phi_1 & \cdots & \Phi_m \end{bmatrix} \in \mathbb{R}^{N \times m}, \Phi' = \begin{bmatrix} \Phi' \end{bmatrix} \in \mathbb{R}^{m \times N} \); \( B(\theta) = \text{diag}(\beta_1, \ldots, \beta_N) \in \mathbb{R}^{N \times N} \); \( \beta_n(\theta) = f_\theta(x_n)(1 - \phi_n(\theta)) \); \( \Phi = \begin{bmatrix} \tau_1 & \cdots & \tau_N \end{bmatrix} \in \mathbb{R}^{N \times (N+1)} \); and \( \tau_n = \tau(\theta_n) = 1 \).

The posterior in Eq. (7) contains all that is known about the parameters \( \theta \) based on the assumed model class \( M(\theta) \) and the data \( D_N \).

**Bayesian Model Class Selection When Using ARD Prior**

In the next step, Bayesian model class selection is used to select the most probable hyperparameter \( \tilde{\alpha} \in \mathbb{R}^{m+1} \). The most probable model class \( M(\tilde{\alpha}) \) based on data \( D_N \) is given by finding \( \tilde{\alpha} \) that maximizes the probability \( p(\alpha|D_N) = \max p(D_N|g)p(\alpha|g) \) for model class \( M(\alpha) \). If a uniform prior on \( g \) is considered, then it is equivalent to the maximization of the evidence \( P(D_N|\alpha) \), which is equivalent to the maximization of the integral over the prior distribution \( p(D_N|g) \) given by
\[ L(\alpha) = \ln \left[ \int P(D_N|g)p(\alpha|g)d\alpha \right] \]
\[ = \ln \int P(D_N|\alpha)p(\alpha)d\alpha \]
\[ = \ln \int P(D_N|g)p(\alpha|g)d\alpha \]
\[ = \frac{1}{2} \left\{ N \ln 2\pi + \ln|B^{-1} + \Phi A^{-1} \Phi'| + \tau(\Phi^{-1} + \Phi A^{-1} \Phi')^{-1} \tau \right\} \]
\[ = \frac{1}{2} \left\{ N \ln 2\pi + \ln|C^{-1}| + \tau(\Phi^{-1} + \Phi A^{-1} \Phi')^{-1} \tau \right\} \tag{8} \]

where \( C^{-1} = B^{-1} + \Phi A^{-1} \Phi' \). The maximization of \( L(\alpha) \) is performed by maximizing \( \alpha \) as follows:

\begin{align*}
L(\alpha) &= -\frac{1}{2} \left[ N \ln 2\pi + \tau(\Phi^{-1} + \Phi A^{-1} \Phi')^{-1} \tau \right] \\
&= \frac{1}{2} \left[ \ln(\tau(\Phi^{-1} + \Phi A^{-1} \Phi')^{-1} \tau) \right] \\
&= \frac{1}{2} \left[ \ln(\tau(\Phi^{-1} + \Phi A^{-1} \Phi')^{-1} \tau) \right]
\end{align*}

where \( C^{-1} = \text{covariance matrix} \ C \) with the components of \( \tau \) removed and therefore \( C^{-1} \) does not depend on \( \alpha \), only on the other components of \( g \). By setting the derivative of Eq. (9) with respect to \( \alpha \), zero, the value that maximizes \( L(\alpha) \) is found to be
\[
\alpha_j = \begin{cases} 
\frac{\hat{S}_j}{\hat{S}_j^2} & \text{if } \hat{Q}_j^2 \leq \hat{S}_j \\
\frac{\hat{S}_j^2}{\hat{Q}_j^2} & \text{if } \hat{Q}_j^2 > \hat{S}_j 
\end{cases}
\tag{10}
\]

Starting with an initial estimate of \( \hat{\alpha} \), \( \hat{\alpha} \) is iteratively calculated from Eq. (10) for each \( j = 0, \ldots, m \), always utilizing the latest estimates for the \( \alpha_j \) to evaluate \( C(\alpha_j) \), and this procedure is continued until it converges to \( \hat{\alpha} \). In this process, some of the \( \alpha_j \) may become infinite, resulting in a pruning of the corresponding components of \( \tau \); since \( \alpha_j \rightarrow \infty \Rightarrow \hat{\alpha}_j \rightarrow 0 \) and \( \hat{S}_j \rightarrow 0 \), so \( \theta_j \rightarrow 0 \) from Eq. (7). Thus, only the components that have \( \alpha_j \) finite are used in determining the separating boundary, so that the maximization of the evidence with respect to \( g \) automatically determines which terms in \( f_{\tilde{\alpha}}(\theta) \) in Eq. (1) are relevant for classification.

**Prediction Phase**

Based on the results from the previous subsection, prediction is performed as follows. Let \( \tilde{y} \) denote the unknown label for new feature, \( \tilde{x} \), then the desired probability is given by
\[ P(\tilde{y} = y|\tilde{x}, D_N) = \int P(\tilde{y} = y|\tilde{x}, \theta, g|D_N) p(\theta|g) d\theta \]
\[ = \int P(\tilde{y} = y|\tilde{x}, \theta, g|D_N) p(\theta|g|D_N) d\theta \]

Using Laplace’s approximation twice
\[ P(\tilde{y} = y|\tilde{x}, D_N) \approx \int P(\tilde{y} = y|\tilde{x}, \theta, g|D_N) p(\theta|g) d\theta \approx P(\tilde{y} = y|\tilde{x}, \hat{\theta}(g)) \tag{11} \]

where \( \hat{\theta}, \hat{g} \) = most probable values for \( \theta, g \) based on data \( D_N \) determined as in Eqs. (7) and (10), respectively, and \( P(\tilde{y} = y|\tilde{x}, \hat{\theta}(g)) \) is given by Eq. (2). Notice that the predictive probability in Eq. (11) is controlled by the optimal boundary function \( f_{\tilde{\alpha}}(\tilde{x}, \hat{\theta}(\hat{g})) \) given by Eq. (1).

**Near-Source versus Far-Source Classification Results**

**Function for Separating Boundary**

In a previous study that used a fixed prior (instead of the ARD prior), the three-parameter model given in Eq. (12) was found to give the optimal separating boundary function based on the earthquake dataset described in Table 1 (Yamada et al. 2007)
Based on the misclassification rates, it could be concluded that the corresponding classification rates for FS data are 23.00 and 2.02% for NS and FS data, respectively. The misclassification rates for \( M_1 \) are 22.00 and 2.02% for the NS and FS data, respectively.

Since \( M_1 \) was estimated by using a constant standard deviation of 100 (\( = \sigma_i^{(2)} \)) for the Gaussian prior for each \( \theta \), the proposed method of Bayesian learning with the ARD prior is first applied to a model class with the same features as in Eq. (12) but using an independent variance \( \sigma_i \) for each \( \theta_i \) (\( i=0,1,2 \)) in the prior. The procedure described in the previous section is applied to the earthquake dataset and the optimal boundary function for this model class \( M_2 \) is given in Eq. (13): the corresponding misclassification rates are 23.00 and 2.02% for NS and FS data, respectively. The corresponding prior variances are given later.

\[
M_1: f(\hat{\theta}) = 6.046 \log_{10} Z_a + 7.885 \log_{10} H_a - 27.091 \quad (12)
\]

This corresponds to a model class, denoted as \( M_1 \), here, that was selected by finding the most probable model class among 255 (=2^8-1) models consisting of all possible combinations of the eight features in Table 2 and using a fixed Gaussian prior \( p(\theta | M) \) for each model class \( M \). The misclassification rates for \( M_1 \) are 22.00 and 2.02% for the NS and FS data, respectively.

Finally, the proposed methodology of Bayesian learning with the ARD prior is applied to a model containing all eight features in Table 2. It produces a five-parameter model class \( M_3 \) whose optimal separating boundary function is

\[
M_3: f(\hat{\theta}) = 2.055 \log_{10} H_a + 5.350 \log_{10} Z_a + 4.630 \log_{10} H_d + 1.972 \log_{10} D_a - 30.982 \quad (14)
\]

Note that for \( M_2 \), the Bayesian learning algorithm is restricted to have no more than \( \log_{10} Z_a \) and \( \log_{10} H_a \), the features that are used for \( M_1 \), while \( M_3 \) selects four features from a potential of eight by automatically pruning the other features. The corresponding misclassification rates for \( M_3 \) are 18.00 and 1.85% for NS and FS data, respectively, significantly smaller than those for \( M_1 \) and \( M_2 \).

The coefficients for the optimal separating boundaries, the prior variances, and the corresponding classification results for each model class are summarized in Tables 3–5, respectively. The performance of these three model classes is next examined by leave-one-out cross-validation and then by calculating their evidence based on the earthquake data \( D \).

### Leave-One-Out Cross-Validation

Table 5 shows the classification results for models \( M_1 \), \( M_2 \), and \( M_3 \) using all 695 records in the earthquake dataset for both training and predicting the labels. As shown in this table, \( M_3 \) outperforms the two other models on the basis of smaller misclassification rates. For another check on the performance of these three models for predicting the class, leave-one-out cross-validation (LOOCV) is performed.

LOOCV, as the name implies, takes one data point at a time from the whole dataset and then a prediction is made based on the optimal separating boundary determined from the remaining data. This procedure is repeated until each data point has been com-

pared with the corresponding prediction (taken here as the class with the higher predictive probability, that is, the class with probability exceeding 0.5). Actually, LOOCV is equivalent to $K$-fold cross-validation where $K (=695$ here) is equal to the number of data in the original dataset. Note that LOOCV is commonly used in Tikhonov regularization to select the regularizing parameter, but this is handled automatically in the Bayesian approach presented here.

The results of LOOCV for each model class are presented in Table 6. Based on the misclassification rate, which is the ratio of the number of misclassified data to the total number of data, classification model $M_3$ shows a better performance.

**Posterior Probability of Each Model Class**

In this section the posterior probability of each model class in the set $M = \{M_1, M_2, M_3\}$ is computed based on the dataset $D_N$ of 695 records by using Bayes’ theorem

$$P(M_i|D_N) = \frac{P(D_N|M_i)P(M_i)}{\sum_{i=1}^{N_i} P(D_N|M_i)P(M_i)} \tag{15}$$

where $P(D_N|M_i)$=evidence for $M_i$; $P(M_i)$=prior reflecting the initial choice of the probability of each model class in set $M$, and the denominator $P(D_N|M_i)$=normalizing constant. Assigning equal prior probability to each model class, the posterior probability of each model class is proportional to its evidence

$$P(M_i|D_N) \propto P(D_N|M_i) \tag{16}$$

Using the theorem of total probability, the evidence is calculated from

$$P(D_N|M_i) = \int P(D_N|\theta_i,M_i)P(\theta_i|M_i)d\theta_i \tag{17}$$

This is the average value of the likelihood weighted by the corresponding prior probability over all possible values of the parameters $\theta_i$. For a large number of data, an asymptotic approximation can be applied to the integral in Eq. (17) (Beck and Yuen 2004)

$$P(D_N|M_i) \approx P(D_N|\hat{\theta}_i,M_i)\left[\frac{(2\pi)^{N_i/2}|H(\hat{\theta}_i)|^{-1}}{\exp(-N_i)}\right] \tag{18}$$

where $\hat{\theta}_i=$most probable value of $\theta_i$; and $N_i=$number of parameters in model class $M_i$. The first factor in Eq. (18) is the likelihood and the remaining factors together are the Ockham factor. This Ockham factor penalizes more complex models. The Hessian matrix $H(\hat{\theta}_i)$ in Eq. (18) is given by the same expression as for $\tilde{\Sigma}^{-1}(q)$ after Eq. (7) where each variance $\alpha_j^{-1}$ is given in Table 4. The posterior probabilities for each of $M_1$, $M_2$, and $M_3$ are presented in Table 7, which shows that $M_3$ is much more probable than $M_1$ and $M_2$ based on the dataset $D_N$.

$^a$These values are natural logarithms of the Ockham factor, likelihood, and evidence, respectively.

$^b$Probability is calculated from the evidence on the basis that the $M_i$ ($i=1,2,3$) are equally probable a priori.

There is a refined information-theoretic interpretation (Beck and Yuen 2004; Muto and Beck 2008) of the log evidence that shows that it consists of the difference between a datafit term (the posterior mean of the log likelihood function for the model class) and a relative entropy term (Shannon 1948) which quantifies the amount of information extracted from the data by the model class. It is the latter term that prevents over-fitting to the data and which leads to an automatic principle of model parsimony (Beck and Yuen 2004) when Bayesian updating is performed over a set of model classes, as done here. This information-theoretic interpretation is evident from the asymptotic approximation Eq. (18) for large $N$ which shows that the log evidence is approximated by the sum of the log likelihood of the most probable model in the model class and the log Ockham factor, which is an asymptotic approximation for the negative of the relative entropy. This is how it was originally discovered (Beck and Yuen 2004) but more recently it has been proven for the general case (Muto and Beck 2008).

**Effect of Prior**

As we stated, the likelihood in Eq. (18) calculated for a more complex model is usually larger than that for a simpler one, since a more complex model gives a better fit to the data (e.g., see Table 7). Therefore, if a model is selected that maximizes the likelihood alone, it tends to prefer the more complex model and may lead to an over-fitting problem. In the Bayesian learning method, this problem is inherently avoided by employing a prior distribution where the standard deviation of the prior controls the trade-off between the datafit error and model complexity (Bishop 2006). This trade-off occurs because the posterior probability of a model class depends on the evidence for the model class, which can be expressed as the product of a datafit factor and an Ockham factor, as explained in the previous subsection.

It is interesting that in the application here $M_1$ is a “simpler” model than $M_3$ (it has fewer parameters) and yet Table 7 shows that its Ockham factor is much smaller than that of $M_3$, so the “simpler” model is penalized more than the more complex one. This is a precaution that one cannot simply count the number of uncertain parameters $N_i$ in a model class $M_i$ to judge its complexity. For the same reason, one must be cautious in using simple model selection criteria such as Akaike’s information criterion (Akaike 1974) and Bayesian information criterion (Schwarz 1978), since they replace the Ockham factor in Eq. (18) with $\exp(-N_i)$ and $\exp(-1/2N_i \ln N_i)$, respectively.

The reason for the lower Ockham factor for $M_1$ is that it has much larger prior standard deviations than $M_3$, so the change in entropy from the very broad prior PDF of $M_1$ to its narrow posterior PDF is very large, and as a consequence the relative entropy term in the information-theoretic interpretation mentioned in the
previous subsection is larger for \( M_1 \) than for \( M_3 \). This interpretation shows that the correct measure of “complexity” for a model class is the amount of information that it extracts from the data, so in this sense, \( M_1 \) is actually more complex than \( M_3 \).

Concluding Remarks

A novel method of Bayesian learning with the ARD prior is presented and applied to classify earthquake ground motion data into NS and FS. The extracted features correspond to the \( \log_{10} \) values of peak jerk, acceleration, velocity, and displacement in the horizontal and vertical directions and these are used with Bayesian learning to establish a separating boundary in the feature space. The ARD prior plays an important role by promoting sparsity when selecting the important features (i.e., by utilizing only a small number of relevant features after automatically pruning the remaining features).

The discussion in the previous subsection and the results presented for the NS/FS classification problem demonstrate that broad prior PDFs should be used with caution when defining a model class. An important advantage of using the ARD prior is that model class selection automatically chooses an appropriate prior that does not overly penalize complexity; it provides a balance between the datafit of the model class and its complexity in terms of the amount of information that it extracts from the data.

The selected most probable separating boundary for classification of seismic signals into NS and FS is

\[
f(\mathbf{x}|\hat{\theta}) = 2.055 \log_{10} H_j + 5.350 \log_{10} Z_a + 4.630 \log_{10} H_v + 1.972 \log_{10} H_d - 30.982
\]

where \( H_j, Z_a, H_v, \) and \( H_d \) are horizontal jerk, vertical acceleration, and horizontal velocity and displacement, respectively, of the ground motion record. Based on Eq. (19), the probability for new data with features \( \mathbf{x} \) to be classified as NS (\( \bar{y}=1 \)) or FS (\( \bar{y}=0 \)) is

\[
P(\bar{y}=1|\mathbf{x}, \hat{\theta}) = \frac{1}{1 + \exp(-f(\mathbf{x}|\hat{\theta}))}
\]

\[
P(\bar{y}=0|\mathbf{x}, \hat{\theta}) = 1 - P(\bar{y}=1|\mathbf{x}, \hat{\theta})
\]

The proposed method is readily applied to real-time analysis of recorded seismic ground motions for NS and FS classification since the only calculations involved are those implied by Eqs. (19)–(21).

In view of the results so far achieved, it can be concluded that it is beneficial to use the proposed Bayesian learning with the ARD prior because it leads to:

1. Higher correct classification rates (equivalent to a lower misclassification rate) (see Table 5);
2. Better generalization performance as demonstrated by the leave-one-out cross-validation results (see Table 6); and
3. The most probable model class based on the calculated posterior probability (see Table 7).

Additional studies are underway in performance-based earthquake engineering in order to apply the method to develop component fragility functions for multiple engineering demand parameters and multiple damage states.
